Disturbance

**ABSTRACT**
Rotation forestry including clearcutting is a common method of practising forestry in Fennoscandia. Clearcutting in peatland forests markedly increases environmental loading: leaching of nutrients and methane (CH\(_4\)) and nitrous oxide (N\(_2\)O) fluxes from soil. Continuous cover forestry has been suggested as an alternative because it does not include clearcutting but partial harvesting. However, impacts of partial harvesting on greenhouse gas fluxes are not well understood and in peatlands have not been studied at all. We conducted a partial harvest by removing 70% of the total stem volume in a mature nutrient-rich peatland forest in Southern Finland. The aim was to investigate how partial harvesting a peatland forest affects CH\(_4\) and N\(_2\)O balances, and how much different surface types contribute to the balances. We used automatic and manual chamber methods to measure fluxes from both harvest and uncut control site. Fluxes were measured from the forest floor, logging trails, and ditches. Fluxes from these surface types were upscaled to obtain net ecosystem-level fluxes during two post-harvest summers (June–August 2016 and 2017). After the harvest, forest floor CH\(_4\) fluxes did not change significantly at the harvested site compared to the control site. However, fluxes at logging trails increased significantly. N\(_2\)O fluxes increased at the harvest site in the post-harvest years, but so did those at the control site as well. Upscaling CH\(_4\) fluxes to ecosystem-level indicated that despite their small area (2.4%), emissions from ditches could be large on ecosystem-scale, but their uncertainty was high, while the logging trail CH\(_4\) fluxes (20% of the total area) were small. In contrast, N\(_2\)O fluxes from ditches were low, but the logging trail fluxes comprised 35–38% of the total surface balance. The overall conclusion is that partial harvesting did not cause considerable changes in CH\(_4\) and N\(_2\)O fluxes from a forestry-drained peatland.

**Introduction**

The most important greenhouse gases (GHG) behind climate change, after carbon dioxide (CO\(_2\)), are methane (CH\(_4\)) and nitrous oxide (N\(_2\)O). Their atmospheric concentrations are much smaller than that of CO\(_2\), but due to their stronger radiative forcing on per-mass, CH\(_4\) and N\(_2\)O constitute about 20% and 7% of the global radiative forcing (Myhre et al., 2013), therefore significantly contributing to global climate change. Peatlands store about a third of the global soil carbon (C) pool (Gorham, 1991; Turunen et al., 2002), making them an essential part of global C and nitrogen (N) cycles and contributing significantly to ecosystem-atmosphere exchange of CH\(_4\) and N\(_2\)O. They cover ca. 3% of the Earth’s land surface (Clarke and Rieley, 2010), and most of them are located in the boreal region (Fischlin et al., 2007).

About 15 million hectares of the boreal peatlands and more than half of the original 10 million ha mire area in Finland has been drained for forestry (Päivänen and Hännell, 2012). Forestry on peatlands, where drainage of the site is one of the most profound measures, affects the conditions for CH\(_4\) and N\(_2\)O production significantly. Drainage of peatlands lowers the WTL, which leads to increased oxygen availability in the peat soil above the WTL (Prévost et al., 1997), and thus decreases the CH\(_4\) fluxes from the soil. This is because the CH\(_4\) production ceases in the oxic peat, but also because there is more CH\(_4\) oxidation in the thicker oxic peat layer. In minerotrophic sedge-dominated mires, an even more important factor is the disappearance of sedges following drainage: the input of easily decomposable substrate (labile C) to the

anoxic peat layers through sedge roots (Joublon et al., 1999) ends, and so does the transport of CH4 from the anoxic layers to the atmosphere through sedge aerenchyma. However, the drainage ditches still emit CH4 and may negate much of the emission-reducing impact of the drainage (Minkkinen et al., 1997; Minkkinen and Laine, 2006). Drainage typically increases N2O fluxes only from fertile/nutrient-rich sites (Martikainen et al., 1993). In peatlands, high N2O fluxes occur mainly from sites with a soil C:N-ratio lower than 25 (Ermfors et al., 2008; Klemetsson et al., 2005). About 40% of drained peatlands in Finland represent herb-rich and Vaccinium myrtillus types (Korhonen et al., 2017), with C:N-ratios typically below 25 (Minkkinen et al. 2020, unpublished results).

Rotation forestry, which is the most common forest management method in Finland and other Nordic countries, includes clearing with stem wood harvest at the end of the rotation. Most of the logging residues produced in the harvesting operation are typically placed on the logging trails to create support for the heavy harvesting machinery, and after the harvest, the residues are either collected or left on the site. After clearing cutting, the site is typically mounded or harrowed, and the new tree seedlings are planted or seeds sown. In addition to a radical change in hydrological conditions, the soil preparation method after clearing cutting influences the CH4 and N2O fluxes (Pearson et al., 2012). Clear cutting has been shown to switch forest sites from net CH4 sinks to sources in both peat (Korkiakoski et al., 2019) and mineral soils (Sundqvist et al., 2014) due to the rise of WTL, although in some studies CH4 fluxes did not change significantly despite increased WTL (Huttunen et al., 2003; Saari et al., 2009). According to Ojansen et al. (2010, 2013), CH4 emissions only increase when the WTL is higher than ~30 cm. Also, N2O emissions usually increase after clear cutting (Huttunen et al., 2003; Korkiakoski et al., 2019; Neill et al., 2006; Robertson et al., 1987; Saari et al., 2009), although contrary results with no effect have also been reported (Nieminen, 1998). The reasons behind the increase in N2O fluxes are unclear, but logging residues have been suggested to enhance N2O fluxes (Mäkiranta et al., 2012). Clear cutting has also been shown to influence forest micrometeorology by changing surface albedo, net radiation, surface roughness and consequently the energy fluxes (McCaughhey & Brintnell 1984; Amiro 2001; Rannik et al. 2002; Kowalski et al. 2003), which indirectly affect CH4 and N2O exchange between soil and the atmosphere.

Shifting from rotation forestry towards methods applied in continuous cover forestry (CCF) has been suggested to mitigate the harmful environmental impacts resulting from clearcutting in peatlands (Nieminen et al., 2018). In CCF, only part of the tree stand is removed in cuttings. The cuttings usually include harvesting from above and below (bigger and smaller trees), so that the remaining stand can grow larger and the open places are naturally regenerated. Thus the stand is typically uneven-aged and uneven-structured, it is never clear-cut, and the forestry is not based on stand rotations. The effects of partial harvesting have been studied on various upland forests (Li et al., 2010; Mazza et al., 2019; Sundqvist et al., 2014) but measurements from peatland forests are lacking.

This study investigates how partial harvesting in a mature, drained boreal pine-dominated peatland forest affects the exchange of CH4 and N2O between the forest floor and the atmosphere, and what is the contribution of ditches and the logging residues and trails on site-level CH4 and N2O balances. WTL raise after partial harvesting is expected to remain smaller than after clear cutting, and therefore, CH4 emissions should increase less than after clear cutting. Also, N2O emissions are expected to increase from pre-harvest conditions as mineral N is liberated from decomposing logging residues while fewer trees are taking it up. In this study, the purpose of the partial harvesting was to regenerate the stand naturally by releasing the spruce understorey, leaving most of the birches for contributing to the transpiration potential of the retained stand and as shelter wood for the desired new spruce seedlings expected to show up after harvesting. Should the transpiration potential of the retained stand prove sufficient regarding drainage and, thereby, proper recovery and future growth of the released understorey, ditch network maintenance may not be needed in this connection. Further, with sufficient regeneration of new seedlings, the development towards an uneven-structured, mixed birch-spruce stand could be enabled.

2. Materials and methods

2.1. Site description

The measurements were carried out in a nutrient-rich peatland forest called Lettosuot located in southern Finland (60°38′ N, 23°57′ E). The site was sparsely drained in the 1930s, but proper drainage was carried out in 1969. After the drainage, the site was fertilised with phosphorus and potassium. The distance between the ditches is on average 45 m, and they were dug ca. 1 m deep but have since been partially filled with vegetation. Before partial harvesting in 2016, the two-storeyed tree stand was composed of Scots pine (Pinus sylvestris) with some pubescent birch (Betula pubescens) in the dominant tree storey with stem numbers of 470 and 190 per ha, dominant heights of 21 and 18.5 m, and standing stem volumes of 184 and 41 m3 ha−1, respectively. The understorey included mostly Norway spruce (Picea abies) (ca. 1000 stems ha−1; 34 m3 ha−1) and some small-sized pubescent birch (ca. 450 stems ha−1; 7 m3 ha−1). The tree stand was quite dense, and its irregular shading resulted in patchy and variable ground vegetation. Detailed description of the ground vegetation and soil can be found from (Bruijyan et al., 2017) and (Korkiakoski et al., 2017, 2019), respectively. At present, the site represents the minerotrophic Vaccinium myrtillus site (Mtkg II) of drained peatlands (for the site type classification in more detail, see Vasander and Laine, 2008).

The partial harvesting (hereafter harvesting) at Lettosuot was performed in 2016 in between February 29th and March 16th in an area of 13 ha (Fig. 1a) where all the pine trees (ca. 70% of the total stem volume) were harvested. The logging residues were left at the site, mostly on the logging trails to improve bearing capacity for the harvesting machinery. The trees close to the automatic and manual chambers were harvested without heavy machinery to avoid breaking the measurement setup and instruments. No soil preparation or seedling planting was performed at the harvest site. Also, the ditches were left intact.

A control site of 3.1 ha, with a similar tree stand and vegetation composition (Fig. 1a), located north-east of the harvest site, was left intact. On average, total stem volume on the control site was ca 20% smaller than on the harvest site (245 and 295 m3 ha−1, respectively); this ratio applied similarly to the dominant pine and the understorey spruce. For birch, the basal areas (7.1; 6.8 m2 ha−1) and stem volumes (53; 52 m3 ha−1) were very similar on both sites. When selecting the locations for the intensive study plots (automatic chambers, manual chamber transects), we preferred locations where spruce understoreys were as similar as possible. After harvesting, basal areas of retained spruce around these intensive study plots were 6.8 and 7.4 m2 ha−1, and stem volumes 31 and 43 m3 ha−1, in the control and harvest site, respectively.

2.2. Automatic chamber measurements

The automatic chamber system at the harvest site was the same as used in CO2 flux measurements by Koskinnen et al. (2014) and CH4 flux measurements by Korkiakoski et al. (2017). In addition to the system used by Korkiakoski et al. (2017), we added a N2O gas analyser in the line (see below). A similar automatic chamber system was installed to both the harvest site (Fig. 1c) and the control site (Fig. 1b); however, two different N2O gas analysers were deployed at the control site for a shorter period (Fig. S1).

Both chamber systems consisted of six transparent chambers with dimensions 57 cm x 57 cm x 40 cm (length x width x height). The chambers equipped with a fan, photosynthetically active radiation
(PAR; PQS1 PAR Quantum Sensor, Kipp & Zonen, Delft, The Netherlands) and a radiation-shielded temperature sensor were used with permanently installed steel collars (height 5 cm, inserted at a depth of 2 cm) to cover different ground vegetation compositions (Table S1) around ca. 15 m radius from the measurement cabin containing the measurement instruments. During winter 2016–2017, an extension collar (height 16 cm) was placed between the chamber frame and the soil to raise the frame above the snow level. In addition, there was a soil temperature profile at 5 and 30 cm depths (Pt100, PT4T, Nokeval Oy, Nokia, Finland) about 15 m distance to the chambers at both harvest and control sites. Air temperature was measured with HMP45D (Vaisala oyj, Vantaa, Finland) from top of a mast at 25.7 m height, and from 2 m height at harvest and control site. A more detailed description of the chamber system can be found in Koskinen et al. (2014) and Korkiakoski et al. (2017).

A Picarro G1130 cavity ring-down spectroscopy gas analyser (Picarro Inc., Santa Clara, CA, USA) was used to measure the CH4 and water vapour concentrations with about 4 s interval, and a continuous-wave quantum cascade laser absorption spectrometer (LGR-CW-QCL, Model N2O/CO-23d, Los Gatos Research Inc., Mountain View, CA, USA) was used to measure N2O concentration with 2 s interval. However, at the control site, Gasmet DX4015 based on Fourier transform infrared spectroscopy (Gasmet Technologies Oy, Helsinki, Finland) was also used in 2017 to measure the N2O concentration (Fig. S1). The chambers closed once an hour for six minutes. Linear and exponential regressions were applied for flux calculation as described in more detail in Appendix A. Data was filtered with normalised root mean square (NRMSE) and iterative standard deviation methods (Appendix B).

Snow depth inside the automatic and manual (Section 2.3) chambers was measured 1-2 times per month during winter. The precipitation and air pressure data was acquired from the closest official weather station operated by Finnish Meteorological Institute at Jokiöinen (∼35 km northwest of Lettosuo).

2.3. Manual chamber measurements

2.3.1. Transect and ditch measurements

Manual chamber sampling transects (Fig. 1bc) were set up on harvest and control sites similarly as described in Korkiakoski et al. (2019). Measurements were made between 29 June 2015 and 29 August 2017, mostly during the snow-free periods. The measurement interval mainly varied between one week and one month; however, there were a few longer gaps in autumn 2015 and spring 2016.

To have a spatially representative sampling in relation to the ditches at the harvest and control sites, two parallel flux measurement points were established (located within 2 m from each other) in the ditch and at a distance of 4, 8, 12 and 22.5 m from the ditch (hereafter ‘transect’). 2 cm deep grooves were carved into the soil surface for the chambers, and were renewed when necessary to keep the chamber sealing adequate. However, if the soil surface was frozen, the measurements were not made as it was not possible to seal the chamber properly. No above-ground logging residues were introduced into the manual chamber points. For ditch measurements, extra collars (height 30 cm) were installed into the ditch one hour before the measurement.

The fluxes were measured using a closed-chamber system with an
opaque cylindrical chamber (height 30.5 cm, diameter 31.5 cm) including a mixing fan. The analysis of gas concentrations was made either using (1) a portable analyser or (2) inside-cabin laser analysers which were detached from the automatic chambers during the manual measurements. As a portable analyser, we employed the same Gasmet DX4015 (Gasmet Technologies Oy, Helsinki, Finland), which was also used in the automatic chamber system at the control site. The air circulated in a loop between the gas analyser and the chamber with a closure time of 10–11 min. The portable gas analyser was used at the transects in harvest and control sites in 2015 (Fig. S1). However, after the harvest in March 2016, more precise inside-cabin analysers coupled with the automatic chamber system were exploited in manual measurements at both transects. This method allowed capturing lower fluxes, especially CH₄, more precisely with a shorter closure time (5 min). At the control transect, N₂O fluxes were measured with the Gasmet DX4015 connected to the automatic chamber system, with a 10 min chamber closure time.

2.3.2. Logging trail and residue measurements

Five parallel plots with four different types of measurement points were set up on the harvest site (Fig 1c) at the beginning of May 2016 by installing chamber collars (55 × 55 × 20 cm, length x width x height) 15 cm deep into the soil. The measurements continued until November 2017 (Fig. S1). Two of the points were located on the logging trail where the residues were piled for additional support for the harvesting machinery. The first point was established on the ground compressed by the wheels of the heavy machinery while the second one was set up on the uncompressed ground. The other two points with a small amount and no logging residues were located outside the logging trail. One of these points simulated a case where trees were harvested, but a small amount of residues were left on the ground while the other one simulated an area which was left untouched during the harvest. Each point had a temperature sensor (iButton DS1921G, Maxim Integrated Products) inserted at 5 cm depth. Also, the points on the logging trail had a similar sensor on the soil surface under the residues. The dry mass of the logging residues in each collar was determined in May 2016 as follows: The residues inside the collars were temporarily removed from the collars and divided into five groups: *Pinus Sylvestris* twigs with needles and branches without needles, *Picea abies* twigs with needles and branches without needles, and *Betula pubescens* branches and twigs. The fresh weight of each of these groups was recorded, and then the residues were returned inside the collars. Also, similar sample groups nearby the collars were taken and weighed and dried at 105 °C. After drying the needles were separated from the twigs, and the dry weight of the sample groups was measured. The relations of these dry and fresh masses were used to determine the dry mass of the needles and woody material (branches and twigs) inside each collar (Table S2). The vegetation composition at the points was recorded on 6 September 2016 (Table S3).

The flux measurements were made by exploiting the instruments used in the automatic chamber system similarly to the transect measurements from 2016 onwards (Sect. 2.3.1) using an angular chamber (60 × 60 × 30 cm, length x width x height).

2.4. WTL measurements and calculations

WTL was monitored hourly with automatic probes (TruTrack WT-HR, Intech Instruments Ltd, Auckland, New Zealand; Odyssey Capacitance Water Level Logger, Dataflow Systems Limited, Christchurch, New Zealand) in dipwells (perforated plastic tubes 120 cm long, 3.5 cm diameter) in multiple locations at both partially harvest and control site. Four dipwells were set up at both automatic chamber systems (Sect. 2.2) next to the chambers in December 2015. When the chambers were close to each other, only one dipwell was installed between them. At the transects, dipwells were installed in May 2015 at each four distance (4, 8, 12, 22.5 m) from the ditch next to the chamber points (Sect. 2.3.1). Also, each plot on the logging trails (Sect. 2.3.2) had one WTL probe since May 2016 until October 2017. In addition to WTL measurements next to the chambers, WTL was also monitored around the control and harvest sites. Five dipwells with automatic WTL probes were installed at the control site (Fig. 1a) in June 2016. Also, at the harvest site, six dipwells were installed in June 2016, and 7 additional dipwells were installed in November 2017 (Fig. 1a). All these WTL measurements were later used in flux upsampling (Sect. 2.5). The WTL measured at the logging trail plots was used to estimate the WTL at each point in the plots by taking into account the ground elevation. These estimated WTLs were used in the mixed-model analysis when investigating the environmental variables affecting the logging trail fluxes (Sect. 2.6).

2.5. Upscaling of the CH₄ and N₂O chamber measurements

To upscale the chamber measurements to the whole harvest and control sites, we used a combination of drone and satellite images to identify the sizes of the different surface types at the site. First, the length of the ditches was measured from the drone images assuming a ditch width of 1 m. Due to lack of any data about the wetness of the ditches, we assumed half of the ditches dry like the ditch measured at the control site, and half wet like the measured ditch at the harvest site. For the harvest site, the ditch area was estimated at 0.315 hectares, which was about 2.4% of the total harvest area (13 ha). For comparison, the share of the ditch area was assumed to be the same for the control site as well. The remaining surface type was forest floor, which at the harvest site was further divided to logging trails and non-logging trails while the whole forest floor at the control site was classified as forest floor without logging trails. The width of the logging trails was 4 m. There were usually two logging trails across one strip (width ~40 m); therefore, the area of the logging trails was assumed 20% of the total forest floor area.

The upsampling was performed for summers (JJA) 2016 and 2017 for harvest and control site separately. The upsampling was limited to sumertime only when the measurement interval of all forest floor types was the highest. The method was based on the relationship of daily WTL and CH₄ flux (Fig. S2) and any other possible factors affecting the flux were ignored. However, there was no clear correlation between N₂O flux and environmental variables (data not shown). Therefore, the N₂O flux upsampling was based only on the emission levels of the different surface types and their share of the total area. The ditch fluxes of both gases were gap filled with linear interpolation separately for the ditches located at the harvest and control sites, and later combined by taking a daily mean between the sites. This averaging assumes that 50% of the ditches were wet and 50% were dry and that the harvesting did not affect the ditch fluxes. For the forest floor, daily mean fluxes of automatic, transect and logging trail chamber measurements were binned into WTL bins with a size of 5 cm ranging from ~10 to ~75 cm. The binning was made separately for logging trails and non-logging trail forest floor. Logging trails included the chamber measurements made on the logging trails while the forest floor measurements included the automatic chamber and transect chamber measurements, but also the logging trail chamber measurements made outside the logging trails (Sect. 2.3.2.). Next, the mean flux for each WTL bin was calculated. Then, control and harvest sites were divided into equally sized plots according to the number of automated WTL measurements located around the site in different compass directions. The areal share of ditches, forest floor with logging trails and forest floor without logging trails were assumed to be the same across the plots (for harvest: 2.4%, 20% and 77.6%). The control site had five automated WTL loggers; therefore, it was divided into five plots, and the harvest site, due to a different amount of WTL dipwells in summers (Sect. 2.4.), was divided into 6 and 13 plots in 2016 and 2017, respectively. At each plot, the daily mean CH₄ flux was acquired from the WTL bin corresponding to the daily mean WTL. Finally, the mean fluxes across the plots were
calculated for each surface type and added together to acquire the CH$_4$ balance of the whole forest.

The uncertainty of the upscaling was estimated by taking into account the most significant uncertainty sources. The ditch area uncertainty was estimated at 51%, which included both the uncertainty of the ditch area (10%) and the uncertainty of the wetness of the ditches (50%). We did not know how wet the ditches were, which can have a large impact on the CH$_4$ fluxes. The uncertainties of the forest floor fluxes were estimated from the summertime balance uncertainties (Appendix C) measured by the automatic chambers. The mean uncertainty between the chambers was calculated for the harvest and control site separately for each year. For the ditch and logging trail fluxes, the uncertainty was estimated by dividing the standard error of the mean with the mean summertime flux. The estimated uncertainties and their sizes are shown in Table S4. The errors of the areas and the fluxes were combined with the standard error propagation principle to acquire the total uncertainty of the upscaling.

The flux calculations and data analysis excluding statistical tests mentioned above were made with the Python programming language (Python Software Foundation, version 2.7, https://www.python.org) using NumPy (http://www.numpy.org/), SciPy (http://www.scipy.org/), Pandas (http://pandas.pydata.org/), and matplotlib (http://www.matplotlib.org) libraries. The flux calculation methods for the automatic chambers were the same as used in Korkiakoski et al. (2017). For the fits, the least-squares method was used through the “polyfit” function of NumPy library for the linear regression and the “curve_fit” function of SciPy library for the nonlinear fits.

Fig. 2. Time series of (a) daily mean air temperature ($T_{air}$) and (b) hourly mean soil temperatures at 5 and 30 cm depths ($T_{soil}$) measured at the harvest and control sites, and (c) daily precipitation sum (black) and annual cumulative rainfall sum (blue), and (d) daily mean snow level recorded at the Jokioinen observatory (35 km northwest of Lettosuo) in January 2015—April 2018. The harvesting (red vertical line) was carried out in February–March 2016. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)
2.6. Statistical analysis

Linear mixed-effect model was used for testing the statistical significance of differences in daily mean CH4 and N2O fluxes between the harvest and control sites, and between the years for both automatic and transect chamber measurements. In both cases, the chamber points were treated as a random effect. The linear mixed-effect model was carried out with the R programming language (R Core Team, 2018, version 3.5.0) using ‘lme4’ package (Bates et al., 2015). The normality of the model residuals was visually checked using quantile-quantile plot (Q-Q plot) method. Tukey’s HSD post hoc test was used for comparison of harvest and control sites, and different measurement years for CH4 and N2O fluxes.

The linear mixed-effect model was also used for explaining the CH4 and N2O fluxes. The logging trail (LT, i.e. the point located on the logging trail or not), dry mass of the needles (DMn), total dry mass of the logging residues (DMres, including needles, and branches and twigs of pines, spruces and birches), water table level (WTL) and soil temperature at 5 cm (ST) were included as fixed effects in the initial model. Chamber points were treated as a random effect (u). The best model was selected by using stepwise selection. We started with a full model and reduced the number of variables one by one using the Akaike information criterion (AIC) as the criteria, which was conducted using the drop1 function in R. The initial model including all factors was:

\[
F_{GHG} = \beta_0 + \beta_1 LT + \beta_2 DM_n + \beta_3 DM_{res} + \beta_4 WTL + \beta_5 ST + \beta_6 (u + e)
\]

where \( F_{GHG} \) is either CH4 or N2O flux, \( e \) is the model error, \( \beta_0 \) is the intercept of the model, and parameters from \( \beta_1 \) to \( \beta_6 \) are the regression coefficients of the explaining variables. We used 95% confidence interval (p < 0.05) to determine whether the results were statistically significant.

3. Results

3.1. Meteorological and hydrological conditions

The mean annual air temperature at the nearby (Jokioinen, 35 km northwest of Lettosuo) weather station before the harvest in 2015 was 6.2°C, which was about 1°C higher than the post-harvest mean temperatures in 2016, 2017 (Table 1; Fig. 2a). The annual temperatures of these three years were higher than the long-term (1981–2010) average at Jokioinen weather station (Table 1), which was also reflected in soil temperatures (Fig. 2b). All three winters (DJF) during the measurement period were warmer than the long-term average (Table 1). The mean summer (JJA) temperatures were variable; summers 2015 and 2017 were 0.8°C and 1.1°C cooler, respectively than the long-term average (Table 1), while the mean summer temperature in 2016 was similar to the long-term average. In addition, compared to the precipitation at Jokioinen (Table 1), 2015 and 2017 were slightly wetter while 2016 was drier (Fig. 2c; Table 1). In particular, autumns (SON) 2016 and winter 2016–2017 were much drier, while the springs and summers, were quite similar to the long-term average.

The snow cover was shallower than the long-term average annual maximum every winter during the measurement period (Table 1; Fig. 2d). Only the winter before starting the measurements (i.e. the beginning of 2015) had thicker snow cover than the long-term average annual maximum.

The seasonal inspection of pre-harvest soil temperatures at 5 and 30 cm depth shows that the temperatures were 0.4°C higher at the control than at the harvest site in summer 2015 (Fig. 2b). However, the soil temperatures were on average 0.3°C higher at the partially harvest site in both post-harvest summers in 2016 and 2017 as compared to the control site. The summertime soil surface temperatures measured under the logging residues had smaller diel amplitude than the 2 m air temperature measured at the harvest site, but larger than the soil temperatures (Fig. S3). Also, the diel amplitude of the 5 cm soil temperature was smaller when there were residues on top of the soil. The monthly mean summertime diel amplitude of the 2 m air temperature varied within 7.3–11.2°C, while the surface temperature under the residues varied within 4.0–6.5°C. The mean differences between the air and surface temperature amplitudes were 3.9 and 4.3°C in summer 2016 and 2017, respectively. Similarly, the soil temperatures varied within 1.0–2.0°C with residues on the surface and within 2.4–3.9°C without residues. The mean differences between the soil temperatures with and without residues were 1.7 and 1.5°C for summer 2016 and 2017, respectively.

Comparing the summertime PAR measured from six points at each site during daytime (06:00–18:00, UTC+3) revealed that the light conditions between the sites were quite similar (harvest mean: 41 µmol m−2 s−1, control mean: 32 µmol m−2 s−1). However, after the harvest, the amount of PAR reaching the surface increased markedly (Fig. S4), averaging at 104 and 109 µmol m−2 s−1 in 2016 and 2017, respectively. At the control site, the PAR remained similar to the pre-harvest mean (2016: 31 µmol m−2 s−1, 38 µmol m−2 s−1).

The mean WTL in the harvest (~48 cm) and control (~49 cm) transects were similar during the pre-treatment summer (JJA) in 2015 (Fig. 3). The mean WTL at the harvest site was 10 cm and 14 cm higher than at the control site in summer 2016 and 2017, respectively. There was, however, a lot of spatial variation around the site during summers. Outside the transects, the WTL typically varied within –15 and –45 cm, and –25 and –75 cm (Fig. S5) in the harvest and control sites, respectively.

WTL was higher in the middle of the strip (22.5 m from the ditch) at the harvest site, inferred from transect WTL measurements (Fig. S6). On average, the summertime WTL was 23 cm higher in the middle of the strip when compared to the point located 4 m from the ditch. However, at the control site, there was not such a clear trend, and generally, the WTL was higher at the 12 m point while the WTL was similar at the rest of the points.

3.2. Automatic chamber fluxes

3.2.1. CH4 exchange

CH4 fluxes showed an apparent seasonal variation at both harvest and control sites (Fig. 4a). Generally, the fluxes were close to zero in the February–April period, but noticeable sink started to develop in May after the soil surface had thawed. The soil sink continued increasing until September when the sink started to decrease with decreasing soil temperatures. In February and March, the CH4 flux was close to zero. CH4 emissions were rare and observed only after some heavy rainfall events.

Here we report the CH4 balances in 6-month periods because this allowed us to compare the balances after the harvest directly to those before the harvest. Before the harvest in 2015, the mean half-year (July–December) CH4 balances were ~156 ± 10 mg CH4 m−2 (± uncertainty, see Sect 2.6) and –167 ± 8 mg CH4 m−2 6 months−1 for harvest and control site (Table S5), respectively; and did not differ significantly from each other. The variation between the measurement points was high at both the harvest and the control sites (from –60 ± 5 to –248 ± 57 mg CH4 m−2 and from –75 ± 10 to –215 ± 36 mg CH4 m−2), respectively. After the harvest, in 2016, the half-year net CH4 uptake decreased on average by 44% at the harvest site and by 31% at the control site (Table S5). The net uptake decreased in all 12 measurement points, but the relative and absolute changes varied. Even though the decrease in net CH4 uptake from 2015 was significant (p < 0.001) in both sites, the harvest and control sites still did not differ significantly from each other in 2016. In 2017, the net CH4 uptake at the harvest site was similar to the 2016 values in three measurement points while in the three other points the net uptake decreased further (Table S5). In contrast to the harvest site, the net CH4 uptake at the control site in 2017 was in between the uptake rates measured in 2015.
and 2016 (Table S5). However, the difference in net CH$_4$ uptake was still not statistically significant between the sites on half-annual nor seasonal timescales; in other words, the harvest did not have a significant impact on the soil CH$_4$ uptake, when inferred from the automatic chamber measurements.

3.2.2. N$_2$O exchange

At the harvest site, the magnitude of the N$_2$O fluxes varied markedly between the measurement points. However, the temporal dynamics remained quite similar before and after harvesting. The emissions were typically highest in summer (JJA, Fig. 4b) when on average 34% (April 2016 – March 2017) and 47% (April 2017 – March 2018) of the annual emissions were recorded. In autumn (SON), the emissions were relatively low, but typically in December or January, the emissions increased again after the soil froze ($T_{5cm} < 0 \degree C$). These elevated emissions after soil freezing could last up to three months and have a large contribution to the annual balance. The contribution to annual balance varied between 15 – 48% when inspecting the annual period of April.
2016 – March 2017. The contribution of these elevated winter emissions was higher in points with relatively low annual emissions. Unlike in previous years, no elevated emissions in winter were observed in late 2017 or early 2018. Between elevated emissions in winter and summer, there was a period of low emissions typically in March and April similarly to autumn.

Before the harvest, the half-year (July–December) N\textsubscript{2}O balance at the harvest site averaged at 138 ± 12 mg N\textsubscript{2}O m\textsuperscript{-2} (± uncertainty, see Appendix C), with considerable variation between the measurement points (52 ± 17 – 222 ± 23 mg N\textsubscript{2}O m\textsuperscript{-2}). After harvesting in 2016, all six points recorded increased emissions, but the relative and absolute increases varied (Table S5). The mean N\textsubscript{2}O balance at the harvest site in 2017 was in between the balances of 2015 and 2016 at 277 ± 52 mg N\textsubscript{2}O m\textsuperscript{-2} and was significantly different from previous years (p < 0.001).

At the control site, we only had automatic chamber measurements in 2017. The half-year cumulative emissions from the measurement points C1-C6 averaged at 600 ± 39 mg N\textsubscript{2}O m\textsuperscript{-2} varying from 145 ± 20 to 1449 ± 178 mg N\textsubscript{2}O m\textsuperscript{-2} (Table S5). Comparing this same period to the measurements at the harvest site (mean: 277 ± 52 mg N\textsubscript{2}O m\textsuperscript{-2}) showed that the emissions from the control site were not significantly different during the latter half of 2017. Also, comparing annual periods of 1/2017 – 12/2017 and 4/2017 – 3/2018 did not reveal significant differences between the sites.

### 3.3. Manual chamber fluxes at the transects

Both the harvest and control site acted as CH\textsubscript{4} sinks both before and after the harvest (Fig. 5 and S7a). CH\textsubscript{4} emissions were observed at 12 out of 16 possible points across the sites at least once, but only at five of them emissions were observed more than once. Again, there was a lot of spatial and temporal variation in fluxes, which varied between −484 and 24 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1}, and −158 and 51 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1} during summer (JJA) at the harvest and control site, respectively. At the harvest site, measurement points 4 m from the ditch had significantly higher sink (p < 0.05) in all calendar years than the points farther from the ditch. In contrast, at the control site, the fluxes generally did not differ significantly between the measurement points. Even though the mean pre-harvest summertime CH\textsubscript{4} uptake rate at the control site was only 49% of that of the harvest site (harvest: −95 ± 34 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1}, control: −47 ± 11 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1}; ± standard error of the mean; Fig. 5), the sites were not significantly different. The net uptake decreased after the harvest by 41% (mean flux: −56 ± 6 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1}) in 2016 and remained so also in 2017, both post-harvest summers were significantly different from the pre-harvest summer (2016: p < 0.01, 2017: p < 0.001). At the control site, the post-harvest CH\textsubscript{4} sink was similar to the pre-harvest sink. Comparing the harvest and control sites against each other showed that they did not differ significantly in either of the post-harvest summers.

The pre- and post-harvest N\textsubscript{2}O fluxes were spatially and temporally highly variable at both harvest and control site (Fig. S7b). Before the harvest, the mean summertime fluxes were 178 ± 109 µg N\textsubscript{2}O m\textsuperscript{-2} h\textsuperscript{-1} (± standard error of the mean) and 38 ± 33 µg N\textsubscript{2}O m\textsuperscript{-2} h\textsuperscript{-1} at the harvest and control site, respectively. However, the two sites were not significantly different with respect to mean summer (JJA) N\textsubscript{2}O fluxes before the harvest. At the harvest site, the fluxes did not change significantly after the harvest. At the control site, summertime fluxes in 2017 (mean: 251 ± 37 µg N\textsubscript{2}O m\textsuperscript{-2} h\textsuperscript{-1}) were significantly higher when compared to two previous summers (2015: p < 0.01, 2016: p < 0.001). However, the post-harvest summertime fluxes in 2016 and 2017 did not differ significantly between the harvest and control sites. In conclusion, the transect measurements did not show any significant harvest-related changes in N\textsubscript{2}O fluxes.

### 3.4. Logging trail and logging residue fluxes

Three of the four measurement point types acted most of the time as CH\textsubscript{4} sink; fluxes were varying mostly between −40 and 0 µg CH\textsubscript{4} m\textsuperscript{-2} h\textsuperscript{-1}.
h^{-1}, while the points located in the uncompressed part of the logging trail commonly acted as CH_{4} sources (Fig. 6). In 2016, small CH_{4} emissions (<30 µg CH_{4} m^{-2} h^{-1}) were sporadically observed also from the compressed points on the logging trail, whereas in 2017 the emissions from the compressed points were frequent from all plots except #2 (Fig. S8). The fluxes from the logging trail were also significantly higher when compared to the transect measurements at the harvest site (p < 0.001; Sect. 3.3). The points on the side of the logging trail were mostly CH_{4} sinks in 2016 in all but plot #5 where several relatively high CH_{4} emissions were recorded (> 600 µg CH_{4} m^{-2} h^{-1}; Fig. S8). In 2017, small emissions were also observed on plots #3 and #4 from the points on the side of the logging trail. Also, the emissions on plot #5 increased from the previous year (Fig. 6a; Fig. S8). When inspecting the whole dataset, no significant differences between the point types were found. Also, none of the inspected variables influenced the CH_{4} fluxes significantly. Because plot #5 was noticeably wetter than the other plots, the analysis concerning the dependence of CH_{4} fluxes on environmental variables was also carried out without plot #5 (Fig. 6b). Removing plot #5 enhanced the statistical significance observed in CH_{4} flux between the points in and outside the logging trail (p < 0.01; Table S6). Also, now using the whole dataset the points on the uncompressed part of the logging trail differed significantly from both points outside the trail. Without plot #5, explanatory factors for CH_{4} flux were found, and the best model indicated that the CH_{4} flux was most influenced by WTL (p < 0.001) and the location of the measurement point in or outside of the logging trail (p < 0.02). The model explained 36% of the variation in CH_{4} fluxes, and the contribution of the fixed effects was 24%.

All the plot types acted as N_{2}O source (Fig. 7) during the whole measurement period. During the first two months of the measurements (May–June 2016) the emissions within plots were somewhat similar, but N_{2}O emissions started to increase in July commonly from the points located on the logging trail (Fig. S9). Again, the emissions were highly variable varying within two orders of magnitude, and none of the plot types differed significantly from each other when inspecting the whole dataset. However, the fluxes from the points on the logging trail were significantly (p < 0.03) higher than those outside of the trail. Generally, the daily mean N_{2}O flux over all the points outside the trail was < 200 µg N_{2}O m^{-2} h^{-1} while the mean emissions from the trail were more variable (generally between: 100 – 900 µg N_{2}O m^{-2} h^{-1}; Figs. 7 and S9). Also, the logging trail points had significantly higher emissions than the emissions measured from the forest floor with automatic chambers at harvest (p < 0.01; Sect. 3.2.2; Fig. 5). The best model explaining the N_{2}O fluxes showed that the N_{2}O flux was most influenced by WTL (p < 0.001) and 5 cm soil temperature (p < 0.01) followed by the location of the point on the logging trail (p < 0.02) and the total dry mass of the residues (p < 0.03). The model explained 48% of the variation in N_{2}O fluxes, but it was mostly due to random effects as the r^2 of the fixed effects was only 14% (Table S6).

3.5. Ditch fluxes

The mean CH_{4} emissions from the ditches were significantly (p < 0.001) higher during the whole measurement period at the harvest site than at the control site. However, as the ditches were so different (water-filled at the harvest and moss-filled at the control site) and the number of measurement points in the ditches was small, it was not sensible to estimate the effect of harvest on ditch fluxes. The means of all the measured CH_{4} fluxes from the ditches were 2754 ± 642 µg CH_{4} m^{-2} h^{-1} (± standard error of the mean) and 127 ± 45 µg CH_{4} m^{-2} h^{-1}, and the fluxes varied within 0–10894 µg CH_{4} m^{-2} h^{-1} and
The CH$_4$ fluxes at the water-filled ditch were more substantial at the control site than at the harvest site, which resulted in smaller net CH$_4$ emissions at the control site during both summers. In 2016, the control site acted as a small CH$_4$ sink ($-18 \pm 22$ mg CH$_4$ m$^{-2}$) while in 2017, the site was a small source ($19 \pm 33$ mg CH$_4$ m$^{-2}$).

Both the harvest and control sites acted as N$_2$O sources during the summers (Table 2). At the harvest site, forest floor contributed the most to the ecosystem N$_2$O balance (2016: 65%, 2017: 62%), while the rest of the ecosystem-level N$_2$O emissions originated from the logging trails. The fluxes from the ditches were insignificant. At the control site, only the emissions from the undisturbed forest floor were significant on ecosystem-scale. The N$_2$O emissions at the harvest site ($368 \pm 29$ mg N$_2$O m$^{-2}$) were larger than the emissions at the control site ($120 \pm 39$ mg N$_2$O m$^{-2}$) in 2016. However, in 2017 the emissions increased in both sites, but the increase at the control site was so large that the total emissions became similar between both sites (harvest: $533 \pm 114$ mg N$_2$O m$^{-2}$, control $495 \pm 46$ mg N$_2$O m$^{-2}$). When considering the climatic effect of these gases in terms of their global warming potential up to 100 years with climate-carbon feedbacks (CH$_4$: GWP$_{100}$ = 34; N$_2$O: GWP$_{100}$ = 298; IPCC, 2013), the total emissions of CH$_4$ were on average only 0.8% of the N$_2$O emissions (Table 2).

### 4. Discussion

#### 4.1. Partial harvest has lower N$_2$O and CH$_4$ emissions than clearcutting

In this study, we found that the partial harvesting did not have a significant impact on CH$_4$ and N$_2$O fluxes in a drained nutrient-rich peatland forest when comparing the pre- and post-harvest situations at the harvest site. Decrease in CH$_4$ uptake have previously been observed in partially harvested boreal upland forests (Sundqvist et al., 2014), but increase in CH$_4$ uptake was recorded in a Mediterranean upland forest (Mazza et al., 2019). Papers studying the effects of thinning on N$_2$O fluxes are scarcer, but increases in emissions have been observed (Li et al., 2010). However, it is difficult to compare different thinning studies as the method of thinning varies, which affects the measured greenhouse gas fluxes (Mazza et al., 2019). According to the previous study at the site made in the same time period as this study (Korkiakoski et al., 2019), clearcutting increased N$_2$O emissions markedly and turned the clear-cut forest floor from CH$_4$ sink into a small CH$_4$ source, and raised WTL by 23 cm. Despite a slight increase of 10 – 14 cm in water level, the forest floor at the partial harvest site remained as a small CH$_4$ sink (Fig. 5), which was due to WTL staying mostly under –30 cm (Fig. 3) that has been considered a limit above which CH$_4$ emissions may occur in peatland forests (Ojanen et al., 2010, 2013). Also, the mean annual CH$_4$ balance measured by the automatic chambers (from $–87 \pm 4$ to $–169 \pm 4$ mg CH$_4$ m$^{-2}$ year$^{-1}$) was smaller than measured at the same forest in 2011–2013 ($–219$ mg CH$_4$ m$^{-2}$ year$^{-1}$; Korkiakoski et al., 2017), but still within typical uptake rates of 10–970 mg CH$_4$ m$^{-2}$ year$^{-1}$ reported in drained peatland forests in Finland (Lohila et al., 2011; Minkkinen et al., 2007; Ojanen et al., 2010). It should be noted, however, that the CH$_4$ emissions (mean balance: $0.8$ g CO$_2$-eq m$^{-2}$ summer$^{-1}$) at Lettosuo after partial harvesting and even after clearcutting (Korkiakoski et al., 2019) were negligible compared to N$_2$O emissions (mean balance: $113$ g CO$_2$-eq m$^{-2}$ summer$^{-1}$) when considering their climatic impact in terms of the global warming potential up to 100 years.
global warming potential up to 100 years.

Based on both manual and automatic chamber data, the effect of partial harvest on N\(_2\)O fluxes was not significant. Nevertheless, this means that the partial harvest did not cause a similar increase in N\(_2\)O emissions as the clearcutting of the same forest (Korkiakoski et al., 2019) where the change was apparent. Smaller changes in N\(_2\)O fluxes were expected as clearcutting removes more trees, raising the WTL, produces more logging residues and severely disturbs ground vegetation, which releases a large amount of reactive nitrogen (NO\(_x\), NH\(_x\)). Thus, an increased amount of mineral N is converted to N\(_2\)O as the uptake by vegetation is diminished. Partial harvesting produces less logging residues as not all the trees are harvested, and ground vegetation is less disturbed, except on the logging trails where most of the vegetation is covered by logging residues. Indeed, N\(_2\)O emissions from the logging trails were significantly larger than the emissions outside the logging trails (Fig. 7). Comparing these two harvesting methods at the same site shows that the mean N\(_2\)O flux measured by the automatic (368 ± 10 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\)) and manual chambers (178 ± 109 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\)) after harvesting in summer 2016 is noticeably smaller than at the clear-cut site where the fluxes increased markedly from about zero up to 1000 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\) on average (Korkiakoski et al., 2019). Comparing the automatic chamber measurements made in this study shows that the mean annual N\(_2\)O balances at Lettosuo (0.69 ± 0.06 – 0.92 ± 0.04 g N\(_2\)O m\(^{-2}\) year\(^{-1}\)) are at the higher end of the range (–0.03–0.92 g N\(_2\)O m\(^{-2}\) year\(^{-1}\)) previously reported at drained peatland forests in Finland (Lohila et al., 2011; Ojanen et al., 2010).

4.2. The effect of partial harvesting on CH\(_4\) fluxes

Partial harvesting did not significantly affect the forest floor CH\(_4\) fluxes (Sect. 3.2.1; 3.3). There were significant differences between the years, but these were unlikely due to the harvest as similar changes were observed at the control site as well. Harvesting raised the WTL on average by 10–14 cm due to decreased transpiration. Higher WTL produces more logging residues and severely disturbs ground vegetation, which releases a large amount of reactive nitrogen (NO\(_x\), NH\(_x\)). Thus, an increased amount of mineral N is converted to N\(_2\)O as the uptake by vegetation is diminished. Partial harvesting produces less logging residues as not all the trees are harvested, and ground vegetation is less disturbed, except on the logging trails where most of the vegetation is covered by logging residues. Indeed, N\(_2\)O emissions from the logging trails were significantly larger than the emissions outside the logging trails (Fig. 7). Comparing the automatic chamber measurements made in this study shows that the mean annual N\(_2\)O balances at Lettosuo (0.69 ± 0.06 – 0.92 ± 0.04 g N\(_2\)O m\(^{-2}\) year\(^{-1}\)) are at the higher end of the range (–0.03–0.92 g N\(_2\)O m\(^{-2}\) year\(^{-1}\)) previously reported at drained peatland forests in Finland (Lohila et al., 2011; Ojanen et al., 2010). The decreases in net half-year CH\(_4\) uptakes in both harvest (2016: 49%) and control (2016: 26%) sites (Sect. 3.2.1) are likely attributed to a combination of small fluxes and relatively small surface area (20% of total area). However, even though the ditches constitute only 2.4% of the total harvested area, they could play a considerable role in the total ecosystem CH\(_4\) balance due to their relatively high CH\(_4\) emissions. The CH\(_4\) emissions from the ditches on the ecosystem level were higher than the forest floor sink at the harvest site during both summers and also at the control site in summer 2017 (Table 2). However, the ecosystem-level ditch fluxes had high uncertainty due to high variability in fluxes, and the fact that only two ditches were measured.

In conclusion, the partial harvest site was likely a CH\(_4\) neutral or a small source due to high emissions from the ditches and decreased sink in the forest floor. However, it should be noted that even though the uncertainties were relatively large, even in the worst-case scenario, the site would still be only a small source of CH\(_4\). Also, the climatic impact of CH\(_4\) emissions in terms of global warming potential over 100 years (mean: 0.8 ± 0.6 g CO\(_2\)-eq m\(^{-2}\) summer\(^{-1}\)) is negligible when compared against N\(_2\)O emissions (mean: 113 ± 10 g CO\(_2\)-eq m\(^{-2}\) summer\(^{-1}\)) at Lettosuo.

4.3. The effect of partial harvesting on N\(_2\)O fluxes

Forest floor N\(_2\)O fluxes were temporally and spatially variable at both harvest and control sites, and no significant difference between them was found due to the harvest (Sect. 3.2.2; 3.3). Based on the data from the automatic chambers at the harvest site, the fluxes were significantly different between all the years. However, no such differences were found in the manual chamber measurements. The contradiction between the automatic chamber and manual chamber measurements was at least partly due to the high spatial variation between the plots and due to lower measurement interval in the transect. Despite the slight, unexplained discrepancy between the methods, it is good to note that at the clear-cut site of the same forest (Korkiakoski et al., 2019), a large increase in N\(_2\)O fluxes was observed during the same time period using the same manual measurement system as in this study. Comparing the results of this study to Korkiakoski et al. (2019) suggests that the effect of the partial harvest on N\(_2\)O fluxes was negligible as it was not observable by manual nor automatic measurements.
An interesting result from the automatic chambers was the bimodal behaviour of \( \text{N}_2\text{O} \) fluxes during the year, showing high emissions in summer and in winter (Fig. 4b). This phenomenon has been observed in multiple studies in upland and agricultural sites, and the emissions during these cycles can be a substantial part of annual \( \text{N}_2\text{O} \) balance (Luo et al., 2012; Papen and Butterbach-Bahl, 1999; Peng et al., 2019; Röver et al., 1998). Large emissions after soil thawing can be explained by \( \text{N}_2\text{O} \) accumulation under the ice (Peng et al., 2019; Teepe et al., 2001). Also, increased emissions have been observed when the soil is frozen, which could occur due to increased amount of substrates during soil freezing (Herrmann and Witter, 2002; Matzner and Borken, 2008; Song et al., 2017). These substrates could be used by microbes living in small unfrozen water films in soil pores (Congreves et al., 2018; Papen and Butterbach-Bahl, 1999). The manual chamber measurements showed significant differences in \( \text{N}_2\text{O} \) fluxes between the summers at the control site, but not at the harvest site. This might be attributed to the counteracting effect of harvesting and the environmental conditions: summer 2016 was drier than 2015 which inhibited \( \text{N}_2\text{O} \) emissions at the control, however at the harvest site, the water-level drawdown due to dry conditions was not marked enough to inhibit emissions. The drier summer might thus explain the smaller \( \text{N}_2\text{O} \) emissions in 2016 at the control because low soil moisture has been attributed to relatively low \( \text{N}_2\text{O} \) emissions (Garío et al., 2007; Dalal et al., 2003; Gelfand et al., 2015).

\( \text{N}_2\text{O} \) emissions were higher on the logging trail than on the side of the logging trail (Fig. 7) and on the forest floor measured by the automatic chambers at harvest site (Fig. 5). The \( \text{N}_2\text{O} \) fluxes were significantly correlated with the location on the logging trail, WTL, soil temperature and the mass of the logging residues. The mass of needles did not significantly correlate with \( \text{N}_2\text{O} \) fluxes. However, the model explained only a small part of the variation in fluxes. Thus, other factors such as soil moisture, which is known to drive \( \text{N}_2\text{O} \) fluxes (e.g. Brown et al., 2012), might have had some effect. Soil moisture could have increased due to soil compression, which enhanced denitrification and \( \text{N}_2\text{O} \) emissions. Also, logging residues stabilised soil temperature and possibly moisture by preventing direct sunlight and evaporation which favour mineralisation and nitrification processes in the organic layer of soil (Roberts et al., 2005; Rosén and Landmark-Thelin, 1987). Upscaling fluxes to the ecosystem-level revealed that the \( \text{N}_2\text{O} \) emissions from the logging trails were 35–38% of total site balance (Table 2) making the logging trails an essential part of the ecosystem \( \text{N}_2\text{O} \) balance. However, there was an exception with logging trail plot #5 where WTL was around \(-20 \) cm or higher. The \( \text{N}_2\text{O} \) emissions at that plot were low because the conditions were too wet for nitrification and \( \text{N}_2\text{O} \) production to occur.

5. Conclusions

Partial harvesting a nutrient-rich peatland forest did not affect \( \text{CH}_4 \) or \( \text{N}_2\text{O} \) balances considerably, and the site remained as \( \text{CH}_4 \) neutral and a small source of \( \text{N}_2\text{O} \) even after the harvest. The logging trails acted as a small \( \text{CH}_4 \) source due to soil compression which likely increased soil moisture and decreased \( \text{CH}_4 \) oxidation, but on ecosystem-level, logging trail \( \text{CH}_4 \) fluxes were insignificant. Given the small number of measurements and the large uncertainties related to the ditch \( \text{CH}_4 \) fluxes, the exact quantification of ditch fluxes was not made. However, \( \text{CH}_4 \) fluxes in peatland forest seem to have a negligible climatic impact, even after the harvest.

The emissions of \( \text{N}_2\text{O} \) from the logging trails were significantly higher than from the forest surface where no changes were observed after harvesting. The higher emissions from the logging trails could have been caused by soil compression, which increases soil moisture and enhances denitrification. Also, decomposing logging residues release reactive nitrogen and prevent direct sunlight and evaporation, which favour nitrification processes in the organic layer of soil. On ecosystem-level, the emissions from the logging trails were an essential part of the \( \text{N}_2\text{O} \) balance of the site constituting 35–38% of the total emissions while the forest floor emitted the rest. The fluxes from the ditches were insignificant. Despite capturing the high temporal and spatial variability in \( \text{N}_2\text{O} \) fluxes by different chamber measurement methods, and recording increased emissions from the logging trails, no considerable harvesting effect in \( \text{N}_2\text{O} \) fluxes was observed when compared to the control site.

Overall, the results in this study show that partial harvesting of peatland forests causes less \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) emissions compared to clearcutting. However, the results here show only the impact of partial harvesting for the first two post-harvest years and more measurements are required to make conclusions of long-term effects of partial harvesting in peatland forests.

Supplementary materials

Appendix A. Flux calculation

The fluxes were calculated the same way as described in Korkiakoski et al. (2017) for both gases. Dilution and spectral corrected \( \text{CH}_4 \) and \( \text{N}_2\text{O} \) concentrations reported by Picarro G1130 and LGR N20/CO-23d were used to calculate the fluxes. Even though the lag caused by tubing was taken into account, 30 s from the beginning of each closure data was removed (Korkiakoski et al., 2017) because the flow rate varied slightly in time, and it takes time for the air inside the chamber to mix properly. In short, both linear and exponential regression models were first fitted to the mixing ratio time series using the least-squares approach.

After fitting, the mass flux (\( F \)) was calculated as

\[
F = \left( \frac{\text{d}C(t)}{\text{d}t} \right)_{\text{MPV}} \frac{\text{MPV}}{\text{RTA} \cdot \text{WTL}}.
\] (A1)
where \( \frac{dC}{dt} \) is the concentration change over time from a linear or exponential model at the beginning of the closure, \( M \) is the molecular mass of CH\(_4\) or N\(_2\)O (16.04 and 44.01 g mol\(^{-1}\) respectively), \( P \) is air pressure, \( R \) is the universal gas constant (8.314 J mol\(^{-1}\) K\(^{-1}\)), \( T \) is the mean chamber headspace temperature during the closure, and \( V \) is the air volume of the chamber and the possible collar, and \( A \) is the base area of the chamber or collar. The collar height, snow depth and the height of mosses and other vegetation in the chamber headspace volume were taken into account, ignoring the pore space in the soil and snow. Finally, analyser-specific flux limits were determined to choose between the linear and exponential models (Korkiakoski et al., 2017). If the flux calculated with the linear model was smaller than the limit, then this estimate was considered more robust and used in the later analysis. These limits for the automatic chamber system at the harvest site were 2.5 µg CH\(_4\) m\(^{-2}\) h\(^{-1}\) and 3 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\).

At the control chamber system, the CH\(_4\) limit was the same, but N\(_2\)O limit was 5 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\) for the LGR analyser.

At the control site, the LGR and Gasmet instruments were simultaneously connected to the chamber system in July – December 2017 to compare the instruments. The comparison revealed that the 6 min closure time used in the automatic chambers was not long enough for Gasmet to determine the flux by using exponential regression. Therefore, only linear regression was used to calculate the fluxes when using only the Gasmet analyser in the first half of 2017 (Fig. S1). The N\(_2\)O fluxes calculated from the Gasmet data were generally underestimated by 10–20%, depending on the flux magnitude when compared to the fluxes estimated from the LGR data. This underestimation was corrected for the automatic measurements at the control for Jan-Jul period in 2017.

For the manual chamber measurements, the fluxes were calculated with nearly the same procedure for the data collected from transects and logging trails. The start and endpoints of the chamber closure were visually identified in the flux calculation. The fluxes were calculated similarly to the automatic chamber measurements so that the specific flux limits for the Gasmet analyser were determined to select between the linear and exponential models as explained in (Korkiakoski et al., 2017). The flux limits for the portable Gasmet system were 35 µg CH\(_4\) m\(^{-2}\) h\(^{-1}\) and 45 µg N\(_2\)O m\(^{-2}\) h\(^{-1}\) which is about ten times as high as for the LGR and Gasmet instruments used in the automatic chamber system due to lower precision of the portable gas analyser.

When using the inside-of-cabin analysers to measure the manual chamber fluxes at the logging tail plots and transects in 2016 and 2017, a 5 min closure time was used at the harvest site. However, at the control transect, a 10 min closure time was used because the N\(_2\)O flux was calculated from the data measured with the Gasmet analyser which required a longer closure time to capture the small fluxes more precisely. For the data collected from the control site, the CH\(_4\) flux was calculated by using the first 5 min data acquired from the Picarro analyser. However, N\(_2\)O was analysed the same way as the measurements made with the Gasmet analyser described above. When using the automatic chamber system in logging tail plots and transect measurements, the sampled air was not returned to the chamber, causing underpressure inside the chamber and underestimation in the flux estimation. Because the chambers had a vent-tube, we corrected the leakage with an assumption that the underpressure consisted of ambient air.

In this study, a micrometeorological sign convention is used: a positive flux indicates a flux from the ecosystem to the atmosphere (emission) and a negative flux indicates a flux from the atmosphere into the ecosystem (uptake).

Appendix B. Quality control of the flux data

Same filtering methods were used for CH\(_4\) and N\(_2\)O fluxes measured with the automatic chamber system as in (Korkiakoski et al., 2017). In short, the hardware problems of the chambers were detected by calculating the normalised root mean square error (NRMSE) of the exponential fit to the CO\(_2\) data measured by Picarro analyser and if NRMSE was > 0.05 the CH\(_4\) and N\(_2\)O data were discarded. Also, random spiking was removed by using an iterative standard deviation (±8 standard deviation) filtering with a 14-day window and one-day time step. At the harvest site, 7.5% of the control site, respectively. For N\(_2\)O fluxes, the filtered percentage was similar to the CH\(_4\) fluxes, but the number of accepted fluxes was slightly larger at the harvest site (n = 18525) and markedly lower (n = 6464) at the control site. These differences were attributed to different instrument availabilities. The measurements conducted at the logging tail plots and transect points were checked visually, and only some of the ditch measurements required filtering due to ebullition. The cases of ebullition were visually identified and discarded from further analysis.

Appendix C. Gap-filling and uncertainties of gas balances

The gaps in the automatic chamber data need to be filled to calculate the seasonal and annual balances of CH\(_4\) and N\(_2\)O. All the gap-filling procedures described next were conducted separately for each automatic chamber and gas. First, the gaps shorter than one day were filled with linear interpolation and the daily sums were calculated from this gap-filled data. Next, the gaps longer than one day were filled with linear interpolation of the daily sums. From these gap-filled daily sums, the monthly, seasonal, and annual sums were calculated. However, chamber H5 at the harvest site had a three-month gap in 7–10/2015, and this method of gap filling would have probably induced too big of an error in the monthly balances. So, we gap filled the chamber H5 fluxes with linear regression of last three months in 2015 between the chambers H5 and H4 (r = 0.86), and H5 and H2 (r = 0.89) for CH\(_4\) and N\(_2\)O, respectively.

The uncertainties of the gas balances were calculated based on the method in (Korkiakoski et al., 2017) which included: (1) the random error of the linear/exponential fit in flux calculation and (2) the error caused by gap filling. The random and gap-filling errors were combined with the standard accumulation principle of independent errors to get the total error estimate.
